Abstract

The antiprotozoal effect of saponins is transitory, as when saponins are deglycosylated to the sapogenin by rumen microorganisms they become inactive. We postulated that the substitution of the sugar moiety of the saponin with small polar residues would produce sapogen-like analogues which might be resistant to degradation in the rumen as they would not be enzymatically cleaved, allowing the antiprotozoal effect to persist over time. In this study we used an acute assay based on the ability of protozoa to break down [^{14}C] leucine-labelled *Streptococcus bovis* and a longer term assay based on protozoal motility over 24 h to evaluate both the antiprotozoal effect and the stability of this effect with fifteen hederagenin *bis*-esters esterified with two identical groups, and five cholesterol and cholic acid based derivatives carrying one to three succinate residues. The acute antiprotozoal effect of hederagenin derivatives was more pronounced than that of cholesterol and cholic acid derivatives. Modifications in the structure of hederagenin, cholesterol, and cholic acid derivatives resulted in compounds with different biological activities in terms of acute effect and stability, although those which were highly toxic to protozoa were not always the most stable over time. Most of the hederagenin *bis*-esters, and in particular hederagenin *bis*-succinate (TSB24), hederagenin *bis*-betainate dichloride (TSB37) and hederagenin *bis*-adipate (TSB47) had a persistent effect against rumen protozoa *in vitro*, shifting the fermentation pattern towards higher propionate and lower butyrate. These chemically modified triterpenes could potentially be used in ruminant diets as an effective defaunation agent to, ultimately, increase nitrogen utilization, decrease methane emissions, and enhance animal production. Further trials *in vivo* or in long term rumen simulators are now needed to confirm the *in vitro* observations presented.

Keywords: antiprotozoal activity, *Hedera helix*, hederagenin, saponins, stability

1. Introduction

The manipulation of the rumen microbial ecosystem using plant secondary compounds has proved to be a useful strategy to increase the efficiency of feed utilization by ruminants (Bodas et al., 2012; Wanapat et al., 2012). Plants or their extracts with high concentrations of saponins appear to have the potential to act as natural antiprotozoal agents (Patra and Saxena, 2009a). Protozoa are a normal but non-vital part of the rumen microbiome and can contribute up to 50% of the bio-mass in the rumen (Williams and Coleman, 1992). Because of their predation activity, rumen protozoa have been shown to be highly active in the turnover of bacterial protein in the rumen (Wallace and McPherson, 1987). Moreover, protozoa have been proven to harbour an active population of methanogenic archaea both on their external and internal surfaces (Finlay et al., 1994; Newbold et al., 1995). A recent meta-analysis has shown that the elimination of protozoa from the rumen could increase microbial protein supply to the host by up to 30% and reduce methane production by up to 11% (Newbold et al., 2015).

Saponins are plant secondary metabolites which consist of one or more sugar moieties glycosidically linked to a less polar aglycone or sapogenin (Francis et al., 2002). The sugar portion is generally made up of common monosaccharides, such as D-glucose, D-galactose, D-glucuronic acid, D-xylose, L-rhamnose, and various pentoses which are glycosidically linked as linear or branched oligosaccharides to the sapogenin. Saponins can be broadly classified based on their sapogenin structure as either triterpenoid or steroid saponins (Wina et al., 2005). The presence of different substituents in the sapogenin such as hydroxyl, hydroxymethyl, carboxyl and acyl groups, as well as differences in the composition, linkage and number of sugar chains accounts for significant structural variation and thus their bioactivity (Patra and Saxena, 2009b; Podolak et al., 2010).

Saponins can form irreversible complexes with cholesterol in the protozoal cell membrane causing cell rupture and lysis (Wina et al., 2005). Rumen protozoal species seems to differ in their sensitivity to saponins due to differences in the sterol composition of their cellular membranes leading to the suggestion that feeding saponins might lead to partial defaunation (Patra and Saxena, 2009a). The antiprotozoal effect of saponins is, however, transitory as when saponins are deglycosylated by rumen microorganisms to the sapogenin they become inactive (Newbold et al., 1997; Patra and Saxena, 2009a) which represents a challenge to their practical application in ruminant nutrition. We hypothesized that the substitution of the sugar moiety of the saponin with small polar residues would produce sapogen-like analogues which might be resistant to degradation in the rumen as they would not be enzymatically cleaved, allowing the antiprotozoal effect to persist over time. The aim of this study was to evaluate both the acute anti-protozoal action and the stability of the antiprotozoal effect of chemically synthesised hederagenin, cholesterol, and cholic acid derivatives *in vitro*.

2. Material and Methods

2.1. Hederagenin, cholesterol and cholic acid derivatives

Ripe ivy (*Hedera helix*) fruits were collected from several locations around Bangor (44.8036° N, 68.7703° W, UK), dried at 50°C for two days and milled. Ivy fruit meal (3.79 kg) was extracted with ethanol (15 L) for 6 h, leading to a crude extract (541 g) comprising triglycerides, saponins, oligosaccharides and pigments (anthocyanins). The crude extract was then washed with petroleum ether (3 x 500 mL) and dried overnight at 50°C under vacuum, obtaining a fine powder (368 g) which comprised mainly mixed saponins and

oligosaccharides. Then an additional extraction with n-butanol was carried out, obtaining a refined extract comprising saponins (15% DM). Hederagenin, the aglycone part of the saponins, was obtained via hydrolysis of ivy fruit refined extract in ethanolic solution with aqueous HCl.

Hederoside B, the major saponin present in the fruit extract, was obtained by gravity chromatography (Fluorochem, silica gel 40-60, CHCl₃/MeOH/H₂O; 90:9:1 → 75:22.5:2.5) of the defatted fruit extract. Fractions containing hederoside B were concentrated and subsequently washed with methanol. Nuclear magnetic resonance data (pyridine-d₅) of the obtained compound was in agreement with that reported in the literature (Kizu et al., 1985).

Hederagenin *bis*-esters derivatives (two identical ester moieties at position 3 and 23; Figure 1) were synthesised from the aglycone hederagenin produced above as described in patent application PCT/EP2016062383 (Ramos-Morales et al., 2016).

Cholesterol and cholic acid derivatives (Figure 2) were synthesised following the same methods for esterification of organic molecules, described in patent PCT/EP2016062383 (Ramos-Morales et al., 2016). Hederagenin, cholesterol, and cholic acid derivatives were produced by DSM Nutritional Products and Bangor University.

The purity of the synthesised compounds was established by quantitative nuclear magnetic resonance (qNMR) spectroscopy using a Bruker Ultrashielded 400 spectrometer (Bruker Corporation, Coventry, UK) confirming purities of 80 - 99% for most derivatives except TSB37 and TSB38 which had a purity of 66% and 58%, respectively. It should be noted that the antiprotozoal activity of compounds TSB37 and TSB38 may be either over or indeed underestimated due to the impurities present.

2.2. Measurement of protozoal activity

The effect of hederagenin, cholesterol, and cholic acid derivatives on protozoal activity was measured *in vitro* as the breakdown of [¹⁴C] labelled bacteria by rumen protozoa as described by Wallace and McPherson (1987). Isotope-labelled bacteria were obtained by growing *Streptococcus bovis* in Wallace and McPherson media (Wallace and McPherson, 1987) containing [¹⁴C] leucine (1.89 µCi/7.5 mL tube) as the sole nitrogen source, for 24 h. Cultures were centrifuged (3,000g, 15 min), supernatant discarded and pellets re-suspended in 7 mL of simplex type salt solution (STS; Williams and Coleman, 1992) containing non-labelled leucine (¹²C-leucine, 5 mM). This process was repeated three times to prevent re-incorporation of released [¹⁴C] leucine by bacteria. The labelled bacterial suspension was sampled to determine its radioactivity and then it was used as the substrate in the incubations with rumen fluid.

Rumen digesta was obtained from four rumen-cannulated Holstein-Frisian cows (4 replicates), fed at maintenance level (diet composed of perennial ryegrass hay and concentrate at 67:33 on DM basis). Animal procedures were carried out in accordance with the Animal Scientific Procedures Act 1986 and protocols were approved by the Aberystwyth University Ethical Committee. Rumen digesta was obtained before the morning feeding and strained through two layers of muslin and diluted with STS (1:1). Diluted rumen fluid (7.5 mL) was then incubated with labelled bacteria (0.5 mL) in tubes containing no additive (control) or 0.05, 0.1, 0.5 or 1 g/L of the modified triterpenes or steroids; hederoside B, a natural saponin isolated from ivy fruit, was also incubated at 0.05, 0.1, 0.5 and 1 g/L. Hederagenin *bis*-sulfate disodium salt (TSB38), cholesteryl succinate (TSB39) and lithocholic acid succinate (TSB42) were dissolved in dimethyl sulfoxide (DMSO) at 1% of the incubation volume. The rest of the derivatives and Hederoside B were solubilized in ethanol at 1% of the incubation volume as it has been shown that such concentration of ethanol in rumen fluid should not impair fermentation (Morgavi et al., 2004; Wallace et al.,

2007). Two control treatments with 1% of either DMSO or ethanol were also included in the experimental design. Incubations were carried out at 39°C under a stream of CO₂ and tubes were sampled at time 0 and at 1 h intervals up to 5 h using a syringe with a 19 gauge needle. Samples (0.5 mL) were acidified (by adding 125 µL of 25% (wt/vol) trichloroacetic acid and centrifuged (13,000 × g for 5 min). Supernatant (200 µL), was diluted with 2 mL of scintillation fluid to determine the radioactivity released by liquid-scintillation spectrometry (Hidex 300 SL, Lablogic Systems Ltd, Broomhill, UK). Bacterial breakdown at each incubation time was expressed as the percentage of the acid-soluble radioactivity released relative to the total radioactivity present in the initial labelled bacteria (Wallace and McPherson, 1987).

2.3. In vitro batch cultures

The initial protozoal population in the inoculum used in the incubations was quantified by optical microscope using the procedure described by Dehority (1993) and adapted by de la Fuente et al. (2006). Within the total population (5.34 log cells/mL), 65% were *Entodinium*, 8% *Epidinium*, 21% *Diplodinium*, 3% *Isotricha* and 3% *Dasytricha*.

To estimate the stability of the antiprotozoal effect and measure the influence of the modified triterpene and steroids on fermentation parameters, strained rumen fluid from each cow was diluted 1:2 in artificial saliva solution (Menke and Steingass, 1988). Aliquots (30 mL) of the diluted strained rumen fluid were added anaerobically to 120 mL serum bottles (Sigma-Aldrich Ltd, Dorset, UK) containing 0.3 g of diet composed of ryegrass hay and barley (40:60), previously ground to pass through a 1-mm² mesh screen. Treatments consisted of control incubations (0.3 g of diet only), with either ethanol or DMSO added at 1%, and incubations with the synthesised compounds (diluted in ethanol or DMSO, as

previously described) at 0.5 or 1 g/L of the incubation. To compare the antiprotozoal effect of the synthesised compounds against that of a natural saponin from ivy, hederoside B (dissolved in ethanol) was incubated at 1 g/L. Bottles were incubated at 39 °C under CO₂ receiving a gentle mix before every sampling time. Samples at different time points (0, 4, 8 and 24 h) were collected for visual assessment of protozoa motility. Ciliate protozoa motility was assessed in 30 µL of sample against a common scale when examined at low magnification (x 100) using light microscopy. This evaluation was conducted in less than 1 min/sample to avoid the cell damage originated by the oxygen and temperature exposure. A score between 0 (no whole protozoa evident) and 5 (all genera active) was given according to the scale described by Newbold (2010). Fermentation pattern, in terms of pH and VFA was determined after 24 h of the incubation. A subsample (4 mL) was diluted with 1 mL of deproteinising solution (200 mL/L orthophosphoric acid containing 20 mmol/L of 2-ethylbutyric acid as an internal standard) for the determination of VFA using gas chromatography (Stewart and Duncan, 1985).

2.4. Calculations and statistical analysis

A simple linear regression was conducted to model the relationship between the percentage of radioactivity released (relative to the ¹⁴C-bacterial inoculum) and the time (from 0 h to 5 h), as well as its correlation coefficient. The slope of this trend-line indicated the bacterial degradation rate (as % h⁻¹) by the rumen protozoa and ultimately their activity. Trend line slopes as well as fermentation parameters were analysed statistically by randomized block ANOVA, with individual cows as a blocking term. Inhibition of protozoa activity (% with respect to the control) was analysed using ANOVA with treatment, dose and

their interaction as fixed effects and cow as blocking term. When significant effects were detected across the different doses, means were compared by Fisher's unprotected LSD test.

Protozoal motility was analysed as a Repeated Measures Design, with treatment as main factor and incubation time as subject factor. A stability index, to estimate the persistence of the saponin effect over time, was calculated as the percentage of the motility at 8 h that remained at 24 h. Interaction between treatment and time as a measure of differential temporal dynamics between treatments was also considered. Differences were declared significant at $P < 0.05$ and considered as tendencies towards significance at $P < 0.10$. Genstat 15th Edition (VSN International, Hemel Hempstead, UK) was used.

3. Results

3.1. Acute anti-protozoal activity

The amount of bacteria degraded by protozoa increased linearly ($R^2 > 0.99$) over the 5 h of incubation with both control treatments (with ethanol or with DMSO). For each derivative, the rate of bacterial degradation at different doses as compared with the control is shown in supplemental Table S1. The inhibition of protozoa activity (Table 1) was significantly different between compounds and doses ($P < 0.001$). Derivatives TSB44, TSB45, TSB46, TSB47, TSB52 and TSB42 were more effective in inhibiting protozoa activity than hederoside B, the major ivy saponin. Among the cholesterol and cholic acid derivatives, TSB39, TSB40 and TSB43 were less effective against protozoa than the natural saponin ($P < 0.001$).

3.2. Stability of the antiprotozoal effect and effect on fermentation parameters

221

222 Based on the observed effects of the synthesised compounds on bacterial breakdown
223 by protozoa, the two highest doses of these derivatives (0.5 and 1 g/L) and hederoside B at 1
224 g/L, were tested over 24 h in *in vitro* incubations. Protozoa motility over time was assessed
225 and fermentation parameters were determined after 24 h of incubation. Due to the number of
226 compounds tested, the experiment was carried out in different batches and hence the slightly
227 different values for fermentation parameters between control incubations. To overcome this
228 issue, we have compared the effects of each compound against the control run with the same
229 batch of rumen fluid.

230 Cell motility, measured as an index of protozoa viability, remained unaltered (score of
231 4.8) over the 24 h incubation period in control incubations with ethanol or DMSO (Figures 3
232 and 4). The effect of hederagenin derivatives when added at 0.5 g/L or 1 g/L is shown in
233 Figures 3a and 3b, respectively. Although, 1 g/L of hederoside B decreased protozoa motility
234 at 4 and 8 h of the incubation (with scores of 3.88 and 3.20, respectively), there was a strong
235 treatment x time interaction ($P=0.05$), and protozoal motility recovered afterwards (reaching
236 a score of 4.26 at 24 h), suggesting the expected degradation of the saponin during the
237 incubation. Some of the derivatives, TSB45 and TSB46, showed the same effect as the
238 natural saponin, initially decreasing protozoa motility but with motility recovering after 24 h
239 (treatment x time interaction, $P<0.05$). Other derivatives, TSB24, TSB47, and TSB52, added
240 at 1 g/L, however, resulted in a greater decrease in protozoa activity over time ($P<0.001$;
241 scores of around 3; no motility or activity evident) with no sign of recovery in motility.
242 Indeed, vacuoles were visible at 24 h suggesting protozoal death (scores of 2.15-2.9). Only
243 few of the hederagenin derivatives (TSB33, TSB34, TSB38 and TSB44) did not show an
244 effect on protozoa motility ($P>0.05$) at any of the concentrations tested. Cholesterol and
245 cholic acid derivatives did not seem to be effective in reducing protozoa motility over time as

shown in Figure 4. Only TSB42 when added at 1 g/L showed a slight decrease in protozoa motility after 8 and 24 h of incubation (treatment x time interaction, $P=0.017$; Figure 4b). A stability index, to estimate the persistence of the saponin effect over time, was calculated as the percentage of the motility at 8 h that remained at 24 h (Figure 5). Whereas the compounds located above the origin on the y-axis were stable (persistent effect on protozoal motility at 24 h; e.g. TS24, TSB37, TSB47), those below the origin on the y-axis showed a loss of effect on protozoal motility (recovery of motility after 24 h; e.g. TSB35, TSB46, hederoside B). The derivatives close to or on the origin of the y-axis (e.g. TSB50, TSB51) correspond to those compounds that were less effective against protozoa (scores of about 4.5 at 8 h) but with an effect that was maintained at 24 h.

Neither the natural saponin, hederoside B, nor the modified triterpenes or steroids caused a decrease in pH ($P>0.05$; Table 2); indeed, pH was slightly greater in the presence of TSB35 and TSB37 at 0.5 and 1 g/L ($P<0.001$) in comparison to the control. Similarly, no effect on the concentration of total VFA was observed in incubations with hederoside B or with most of the derivatives ($P>0.05$; Table 3). Only TSB35 and TSB36 caused a reduction in the concentration of VFA ($P<0.05$) when added at 0.5 and 1 g/L. Almost all treatments caused shifts in the molar proportions of VFA towards lower butyrate and higher propionate ($P<0.05$), to different extents depending on the compound (Tables 5 and 6). Also, some of the derivatives decreased the molar proportion of acetate (Table 4; $P<0.05$).

The natural saponin, hederoside B, decreased acetate and butyrate molar proportions by 8 and 18%, respectively, whereas it increased that of propionate by 35%, in comparison to the control. The greatest effect was observed with TSB35 (hederagenin *bis*-glutarate), TSB37 (hederagenin *bis*-betainate dichloride) and TSB47 (hederagenin *bis*-apidate) which, when added at 1 g/L, decreased the molar proportion of acetate and butyrate by 11-13.5% and 35.5-52.7%, respectively, with an increase in propionate of 64.5-84.2%. Cholesteryl succinate

(TSB39) and cholic tri-succinate (TSB41) did not have any effect on the molar proportions of VFA. Cholic succinate (TSB40) caused only a slight decrease in butyrate ($P=0.013$) at 1 g/L, as compared to the control. TSB42 and TSB43 also resulted in decreases in acetate and butyrate and increases in propionate although to a lesser extent than those caused by hederoside B. Molar proportions of branched-chain VFA (BCVFA, i.e. isobutyrate and isovalerate) decreased ($P<0.05$) in incubations with TSB24 (-13%) and TSB38 (-16%) at 1 g/L and TSB50, TSB51, TSB52 and TSB58 at 0.5 and 1 g/L (decreases of 22-24% at 1 g/L; Table 7). TSB43, however, resulted in an increase ($P=0.044$) in BCVFA when added at 1 g/L (+54%; Table 7). This was mainly due to changes in isovalerate rather than isobutyrate (Supplemental Tables S2 and S3).

4. Discussion

The biological activity of saponins depends not only on the type of aglycone but also on the sugar composition and arrangement (Wina et al., 2006). The haemolytic action of saponins is believed to be the result of the affinity of the aglycone moiety for membrane sterols, particularly cholesterol with which they form insoluble complexes. It has been shown that monodesmosidic saponins (a single sugar chain) were generally more active than bidesmosidic ones (two sugar chains) (Voutquenne et al., 2002). A further study (Chwalek et al., 2006) testing different hederagenin diglycosides concluded that even the substitution of a monosaccharide with another monosaccharide within the sugar chain may change biological activity of saponins. As far as we know, no studies on the correlation between the haemolytic activity and antiprotozoal activity or on the relationship between saponin structure and antiprotozoal activity in the rumen have been carried out.

295 Although the antiprotozoal effect of saponins has been consistently shown in *in vitro*
296 studies (Wina et al, 2005), it was also found to be transient (Newbold et al., 1997;
297 Teferedegne et al., 1999). This transient nature has been associated to the degradation of
298 saponins, i.e. the cleavage of the glycosidic bonds towards the aglycone leaving the inactive
299 sapogenin behind, by rumen bacteria rather than to the ability of rumen protozoa to become
300 resistant (Newbold et al., 1997). Makkar and Becker (1997) reported the disappearance of
301 saponins from quillaja over time when incubated with buffered rumen fluid, with a reduction
302 of 50% after 12 h and by 100% at 24 h of the incubation. In the present study, we
303 hypothesized that the substitution of the sugar moiety of the saponin with small polar residues
304 would produce sapogen-like analogues that might be resistant to ruminal degradation. Both
305 the acute antiprotozoal activity and the stability of that effect over 24 h of fifteen hederagenin
306 *bis*-esters esterified with two identical groups (Figure 1), and five cholesterol and cholic acid
307 based derivatives carrying one to three succinate residues (Figure 2) was evaluated. Our 5 h
308 *in vitro* incubations results showed that, irrespective of their resistance to degradation, some
309 of the hederagenin derivatives were more effective in reducing protozoa activity than the
310 natural saponin hederoside B. The greatest effect was shown with TSB45, TSB46 and TSB52
311 which reduced protozoa activity by 63-75% when they were incubated at 0.05 g/L.
312 Interestingly among the cholesterol and cholic acid derivatives, TSB39 (cholesteryl
313 succinate) had the lowest antiprotozoal effect and, TSB42 (lithocholic acid succinate) was
314 one of the most effective compounds tested, decreasing protozoa activity by 75% when added
315 at 0.05 g/L. These results agree with the observations of Takechi et al. (1996), who showed
316 that the biological activity that a specific chemical residue may provide is not transferable
317 from one derivative to another. To study if the synthesised derivatives were still effective
318 against protozoa over a longer period of time, *in vitro* incubations were carried out sampling
319 at 0, 4, 8 and 24 h to assess the stability of the derivatives in a mixed rumen population.

Derivatives TSB24, TSB47 and TSB52 seemed to be very effective in causing a decrease in protozoa motility over time without recovery after 24 h, contrary to the results observed for hederoside B and the rest of compounds. Surprisingly, none of the cholesterol and cholic acid derivatives showed an effect on protozoa motility. Although TSB42 had a strong effect in bacterial breakdown by protozoa over 5 h of incubation, little effect on protozoa motility was observed in 24 h *in vitro* batch cultures. These results may suggest a quicker degradation, and thus the loss of activity, of this compound by rumen bacteria as compared with other derivatives tested. It is apparent that the compounds that showed a high level of acute toxicity against protozoa were not always the most stable ones over time. A stability index was calculated as the percentage of the 8 h activity that remained after 24 h (Figure 5). Even though TSB35 reduced protozoa activity by 93% when added at 1 g/L, this compound was among the least stable derivatives. TSB24 and TSB47, however, showed both high toxicity (reduction of protozoa activity of 95-100%) and stability over time.

Most of the hederagenin derivatives did not influence total VFA concentration. However, shifts in the molar proportions of VFA towards lower acetate and butyrate which was compensated by a higher propionate were observed. These changes have been previously reported when using different sources of saponins (Wina et al., 2005; Patra and Saxena, 2009a; Jayanegara et al., 2014). The shifts in the molar proportions of butyrate and propionate shown in the presence of TSB35, TSB37 and TSB47 were, however, much greater than those that would have been expected because of defaunation. A recent meta-analysis showed that defaunation decreased butyrate by 22% with no effect on propionate (Newbold et al., 2015). It should be pointed out that TSB37 was of low purity (66%) and thus, this hederagenin derivative could have been more effective than others with higher purity. However, it is possible that the effects observed in the presence of TSB37 were due to the impurities in this derivative. Although our target in using the synthesised compounds was to

control protozoal activity, other microorganisms may also have been directly or indirectly affected by the derivatives resulting in further effects on rumen fermentation. Indeed, a direct effect of saponins on bacteria, probably mediated by disruption of the cell membrane (Patra and Saxena, 2009a,b; Bodas et al., 2012), has been reported. Similarly, saponins can exert antifungal activity by the interaction with membrane sterols leading to pore formation and loss of membrane integrity (Goel et al., 2008. Patra and Saxena, 2009a,b).

Clearly modifications in the structure of hederagenin resulted in compounds with different biological activities *in vitro*. Whereas some compounds (TSB24) were more effective in reducing protozoa activity and motility, others (TSB37) caused a substantial increase in propionate. If the effect of these compounds can be confirmed *in vivo*, the use of these modified triterpenes in ruminant nutrition will have the potential to improve the efficiency of nitrogen utilization and decrease methane production thus potential boosting productivity.

Conclusion

Most of the hederagenin *bis*-esters, and in particular hederagenin *bis*-succinate (TSB24), hederagenin *bis*-betainate dichloride (TSB37) and hederagenin *bis*-adipate (TSB47) had a persistent effect against rumen protozoa *in vitro*, shifting the fermentation pattern towards higher propionate and lower butyrate. The confirmation of these effects *in vivo* would help to determine if these novel chemically modified triterpenes could potentially be used in ruminant diets as an effective defaunation agent to, ultimately, increase nitrogen utilization, decrease methane emissions and enhance animal production.

Acknowledgements

This work was financed by the Innovate UK project “Ivy for ruminants” Ref: 101091. CJN acknowledges the support of the Biotechnology and Biological Sciences Research Council, UK via grant number BB/J0013/1. The Authors thank E. Jones and S.E. Girdwood for their technical assistance.

Author’s contribution

ER, SD, CW, MB, ML, DP, RB and CN contributed to the conception and design of the work; ER and GF conducted the research; ER wrote the manuscript; ER, GF, SD, CW, MB, ML, DP, RB and CN reviewed the manuscript. ER and CN had primary responsibility for the final content. All authors read and approved the final manuscript.

Figure legends

Figure 1. Structure of Hederagenin derivatives.

Figure 2. Structure of Cholesterol and Cholic acid derivatives and Hederoside B.

Figure 3. Protozoa motility over 24 h in the absence (control) or presence of different hederagenin derivatives at 0.5 (**A**) and 1 g/L (**B**). Hederoside B was used as a positive control at 1 g/L. Error bars indicate the standard error of the difference for each time point ($n = 4$).

Figure 4. Protozoa motility over 24 h in the absence (control) or presence of different cholesterol and cholic acid derivatives at 0.5 (**A**) and 1 g/L (**B**). Hederoside B was used as a positive control at 1 g/L. Error bars indicate the standard error of the difference for each time point ($n = 4$).

Figure 5. Stability index (calculated as the percentage of the motility at 8 h that remained at 24 h) against motility scores at 8 h in the presence of hederagenin and cholesterol and cholic acid derivatives and hederoside B (HB) at 1 g/L. Error bars indicate the standard error of the difference ($n = 4$).
